ABSTRACT

Aims: To assess the Liver function in COVID-19 infection and study its correlation with inflammatory markers and severity of disease.

Study Design: A Retrospective Observational study.

Place and Duration of Study: Government Kilpauk Medical College, Chennai, India. Two month study period was taken during the second COVID wave (1st May 2021 to 30th June 2021).

Methodology: The study covered all COVID-19 positive individuals who were over the age of 19. Patients with any chronic liver disease, Hepatitis B or Hepatitis C were excluded. Data was collected from case files. Record was made of the liver function tests and inflammatory markers – C-Reactive Protein and Interleukin-6 (CRP, IL-6). Severe disease was defined as patients with respiratory rate > 30/min, SpO2 <90% on room air or requiring Intensive Care Unit (ICU) admission or mechanical ventilation. Collected data was analysed using appropriate statistical tests.

Results: 132 patients were included in the study. Out of these 59 patients (44.70%) had elevated
Liver function tests (LFTs). Maximum patients (42.37%) had hepatocellular pattern. 59.32% patients were males. Mean age of patients with elevated LFTs was 51.03±13.03 years. ICU admission was required in 40.68% of patients with deranged LFTs compared to 23.28% in patients with normal LFTs, which was statistically significant (P <0.03). A positive correlation was found between deranged LFTs and inflammatory markers (CRP, IL-6). (P <0.001).

**Conclusion:** A significant number of COVID-19 positive individuals have abnormal liver function. Inflammatory indicators and elevated LFTs have a positive relationship. Patients with abnormal liver function tests were more likely to have severe illness.

**Keywords:** COVID-19; liver function test; severe disease; inflammatory markers.

**1. INTRODUCTION**

COVID-19 pandemic has afflicted nearly 350 million people around the world till now.[1] SARS-CoV-2 is a highly transmissible virus which can spread from person to person through respiratory droplets during sneezing and coughing. The incubation period of the disease is 2-14 days.

SARS-CoV-2 belongs to the family coronaviridae and belongs to the genus betacoronavirus. Coronavirus is single stranded RNA enveloped virus, of size 62-125 nm. It has four structural proteins known as S (Spike), E (envelope), M (membrane) and N (nucleic acid) [2].

Although COVID-19 patients typically experience respiratory symptoms, additional organ systems have been implicated, resulting in gastrointestinal problems [3] and abnormal liver functioning [4]. Few investigations have found a link between SARS-CoV-2 and liver dysfunction or injury. [4,5] The actual cause of liver impairment in people infected with SARS-CoV-2 is unknown. Direct virus-induced cytopathic effects, worsening of pre-existing liver disease, hypoxemia, drug-induced and overshooting inflammatory responses are all possible mechanisms. It has been postulated that the S protein of SARS-CoV-2 initially binds to the ACE-2 receptors which are found in epithelial cells and tissues of lung, heart, liver, blood vessels, GI tract and kidneys [6] inducing uptake of virus particles.[7,8] ACE-2 receptors are also present in central hepatic vein and portal vein endothelial cells. The binding of SARS-CoV-2 virus to ACE 2 receptors on cholangiocytes may lead to liver dysfunction. [9] Other potential mechanisms include hypoxic changes caused by respiratory failure and drug induced liver injury [10].

Our study aims to assess the liver function in COVID-19 infection and to study its correlation with inflammatory markers and severity of disease.

**2. MATERIALS AND METHODS**

A retrospective observational study was carried out at Government Kilpauk Medical College and Hospital, Chennai, which is a tertiary care centre. The study was carried out over two months period (1<sup>st</sup> May 2021 to 30<sup>th</sup> June 2021), during the second COVID wave. The study covered all COVID-19 positive individuals who were over the age of 19. The study excluded patients with chronic liver disease, hepatitis B, or hepatitis C. The COVID-19 infection cases were detected by real-time reverse transcriptase polymerase reaction (RT-PCR) from nasal or pharyngeal swab. Data was collected from case files. Demographic data (age, gender) was noted. Record was made of the liver function tests and inflammatory markers [C-reactive protein (CRP) and interleukin -6 (IL-6)]. Aspartate aminotransferase (AST) value more than 40 U/L, Alanine aminotransferase (ALT) value more than 40 U/L, alkaline phosphate (ALP) value more than 120 U/L and total bilirubin value more than 1.5 mg/dl were taken as abnormal LFT values.[4] CRP value of more than 5 mg/dl and IL-6 value of 15 pg/ml were considered as elevated inflammatory markers. In the study liver injury was defined as hepatocellular, cholestatic or mixed type by
calculating the R factor. Severe disease was defined as patients with respiratory rate > 30/min, SpO2 <90% on room air and requiring ICU admission or mechanical ventilation.

Collected data was tabulated in MS-Excel. The data was analysed using appropriate statistical tests. Demographic variables were expressed as percentage. Correlation analysis was done by using the Pearson correlation coefficient. P value of <0.05 was considered as statistically significant.

3. RESULTS AND DISCUSSION

132 patients were included in the study who fulfilled our inclusion criteria.

Out of these 59 patients (44.70%) had elevated Liver function tests and the rest 73 had normal LFTs. (Figure 1) Our findings were consistent to other studies like study by Saini RK et al [4] and Priyadarshini BP et al [11] which also suggest that COVID-19 is associated with liver dysfunction in a significant number of patients. According to another Indian study, more than half of COVID-19 patients have multiple liver function test anomalies [12].

3.1 Demographic Profile

Of all the total patients included in the study, 58.33% were males and 41.67% were females.

The pattern of LFT profile amongst the males and females is shown in Fig. 2. Amongst the patients who had deranged LFTs, 59.32% patients were males and 40.68% were females.

Similar to our study, few other studies (Saini RK et al.[4] and Priyadarshini BP et al.[11]) also found a slight male preponderance for COVID-19 infection. Another study done in India by Kaushik A et al reported the percentage of male and females were 60.9% and 39% respectively.[12] A slightly increased predominance amongst the males according to some studies in Wuhan is attributed to higher expression of ACE-2 receptors in males [13,14].
In a study of 148 individuals with COVID-19, Fan et al found that the average age was 50 years old. [15].

In our study, mean age of patients was 47.52 ± 12.06 years in those with normal LFTs and 51.03 ± 13.03 years in those with elevated LFTs.

### 3.2 Liver injury in COVID-19 Infection

Amongst the patients with deranged LFTs, maximum patients (42.37%) had hepatocellular pattern of type of liver injury, followed by mixed pattern in 37% and cholestatic pattern was seen only in 20 %. (Fig. 3).

A study by Xu W et al also showed that the pattern of abnormal liver function tests is predominantly hepatocellular.[16] Cai Q et al however found mixed type of liver injury to be most common [17].

Mean LFTs values amongst those with elevated LFTs were as follows: Mean S. Bilirubin = 3.26 ± 1.03 mg/dl, Mean AST = 195.29 ± 102.71 IU/L, Mean ALT = 211.75 ± 106.89 IU/L, Mean ALP = 177.51 ± 61.42.

On calculating the mean values of the different parameters of LFTs in the 2 groups, it was observed that the elevation in the liver function tests was significant (Table 1).

When compared to patients with lesser forms of COVID-19, patients with severe COVID-19 have greater bilirubin levels. [18] Total bilirubin was found to be significantly increased (<0.001) in patients with abnormal liver enzyme levels and liver injury as compared to patients with normal liver enzyme levels [4].

In study by Saini RK et al., he found, median values of AST, ALT, ALP were found to be 95.0 U/L, 127.7 U/L, 142.0 U/L. [4].

#### Table 1. Comparison of normal LFTs and Deranged LFTs group in COVID-19 patients

</tbody>
</table>

P<0.001 suggests that LFTs are significantly increased in the deranged liver function group

( AST - Aspartate aminotransferase, ALT - Alanine aminotransferase, ALP - Alkaline Phosphatase)
The inflammatory markers were raised significantly. Mean IL-6 was 17.07 ± 13.16 pg/ml and Mean CRP was 18.7 ± 13.7 mg/dl in patients with deranged LFTs.

3.3 Correlation of LFTs with Severity of Disease and Inflammatory Markers

Severe disease was defined as patients with respiratory rate > 30/min, SpO2 <90% on room air and requiring ICU admission or mechanical ventilation. ICU admission was required in 40.68% of patients with deranged LFTs compared to 23.28% in patients with normal LFTs, which was statistically significant (\(P<0.03\)) (Fig. 4).

Among the patients with deranged LFTs, 4 patients expired (6.7%), whereas only 2 deaths (2.7%) were reported in patients with normal LFTs.

RK Saini also conducted a study in which he found 37.07% patients with elevated LFTs and 21.15% with normal LFTs required ICU admissions [4].

On calculating the \(P\)-values amongst the different liver function tests and the CRP and IL-6 values in the group with deranged LFTs, a positive correlation was found between deranged LFTs and inflammatory markers (CRP, IL-6). (\(P<0.001\)) (Fig 5,6).

Our results were consistent with studies by Saini RK et al and Xu W et al who also concluded that patients with abnormal LFTs are at an increased risk of severe disease.[4,16] Also Saini RK et al in their study concluded that patients with abnormal LFTs were associated with raised levels of inflammatory markers and they found a positive correlation between elevated LFTs and CRP [4].

![Fig. 5. Correlation of LFTs with IL-6](image)
4. MANAGEMENT

All the patients were treated according to the COVID-19 protocol guidelines issued by ministry of health and family welfare, Government of India.

5. CONCLUSION

COVID-19 individuals typically have respiratory symptoms, although other organ systems have also been implicated.

A significant number of COVID-19 positive individuals have abnormal liver function. Inflammatory indicators and elevated LFTs have a positive relationship. Patients with abnormal liver function tests were more likely to have severe illness necessitating ICU hospitalisation.
